In vitro drug screening
3D tissue

The ability to accurately detect cardiotoxicity has become increasingly important in the development of new drugs. Since the advent of human pluripotent stem cell-derived cardiomyocytes, researchers have explored their use in creating an in vitro drug screening platform. Recently, there has been increasing interest in creating 3D microphysiological models of the heart as a tool to detect cardiotoxic compounds. By recapitulating the complex microenvironment that exists in the native heart, cardiac microphysiological systems have the potential to provide a more accurate pharmacological response compared to current standards in preclinical drug screening. This review aims to provide an overview on the progress made in creating advanced models of the human heart, including the significance and contributions of the various cellular and extracellular components to cardiac function.

1. Introduction

The heart, like most other organs, is a complex and heterocellular system that has evolved to perform specific functions. The most critical function of the heart is to pump blood to the rest of the body, which is necessary for the transport of oxygen and nutrients to maintain viability. Dysregulation of the cardiovascular system is a major concern in modern society; while the development of new drugs and therapies have helped alleviate this problem, cardiovascular disease remains the leading cause of deaths worldwide [1]. Compounding this problem is the observation that some FDA approved drugs for cardiovascular disease as well as a host of other diseases (e.g., diabetes, inflammation) have subsequently exhibited cardiotoxic side effects, leading to the withdrawal of numerous drugs from the market [2]. New anticancer drugs are among those that have shown unexpected negative cardiac side effects, further prompting the need to improve current methods to screen drugs for possible cardiotoxicity [3,4].

The current standard for preclinical drug screening is animal models, primarily mouse models, which have failed to fully recapitulate the human heart’s response to drugs. Compared to humans, mice...
show profound differences in beating rate (500–724 bpm compared to 60–90 bpm) as well as electrophysiological properties (e.g., electrocardiogram duration, repolarization currents, and ion channel expression levels) [5]. The hERG binding assay has been developed and implemented to screen for drugs that cause hERG-mediated QT prolongation, but this method does not address any other ion channels involved in cardiomyocyte electrophysiology and fails to capture drug-induced cardiotoxicity [6]. The inability to predict human cardiac physiological response to drugs has contributed to higher rates of failure in clinical trials, putting patients at unnecessary risk and raising the overall cost of drug development. A potential solution to the current limitations of screening for cardiac drug toxicity is to develop in vitro models of human cardiac physiology, which could provide better predictive power of potential cardiac toxicity and thus improve the efficiency of drug discovery.

While intriguing, developing in vitro human models of cardiac function is not without significant challenges. Given the complex mechanisms involved in various pathophysiological conditions of the heart, an appropriately complex model will be necessary to study such events [7]. Nonetheless, researchers have put forth significant effort toward creating microphysiological models of the heart, focusing on creating biomimetic cardiac tissue that recapitulates some of the key electrical and mechanical properties of the heart, and thus an accurate pharmacological response. Over the past 5 years, significant targeted funding from the National Institutes of Health (NIH), Defense Advanced Research Projects Agency (DARPA), and the US Food and Drug Administration (FDA) has stimulated interest in engineering microphysiological systems of not only the heart but also other physiological systems (e.g., gastrointestinal tract, brain, and kidney) that will potentially improve drug efficacy and toxicity [8].

This review will present the recent progress in creating microphysiological models of the heart, with an emphasis on drug screening applications. Starting with an overview of cardiac anatomy, we will explore tissue engineering strategies that consider the choice of cellular and extracellular components as well as how to integrate these components temporally and spatially to recover the most important features of cardiac function. Finally, we will discuss the most significant remaining hurdles, and the future outlook for ultimate success.

2. Anatomical considerations

The heart consists of several distinct anatomical units [9]. The four heart chambers and associated valves control the flow of blood in a unidirectional fashion through the heart. The spiral arrangement of ventricular cardiac muscle fibers allow coordinated force generation adequate to pump blood to the rest of the body. Action potentials are generated at the sinoatrial node, and the frequency is modulated by the nervous system. Recreating the complexities of an entire heart is currently intractable – and would likely be cost-prohibitive and unnecessary for drug screening applications. Instead, microphysiological models of the heart have targeted the myocardium, the source of electrical propagation and force generation in the ventricle, as the minimal functional unit that could model drug responses and disease states (Fig. 1). Cardiomyocytes comprise the largest volume of space in the myocardium and demonstrate a highly ordered structure that coordinates action potential propagation and force generation. Adjacent cardiomyocytes form intercalated disks, whereby intercellular junctions promote synchronous contractions via electrical coupling [10]. Connexins, and specifically connexin-43 (Cx43), are the predominant gap junction proteins found between cardiomyocytes and is often utilized as a marker of electrical coupling. The myocardium requires these coordinated electrical and mechanical activities in order to perform its function, and dysregulation can lead to pathological conditions such as reentry ventricular arrhythmia. Single-cell cardiomyocytes cannot model many of these conditions and has led to the development of more advanced models of the myocardium that better mimic physiologically relevant cardiac tissue.

3. Two-dimensional models

Since the advent of human pluripotent stem cell-derived cardiomyocytes (hPSC-CM), researchers have explored their potential use in drug screening [11,12]. Cardiomyocyte differentiation has significantly increased in efficiency and reproducibility within the last decade, helping to develop an accessible source of human cardiomyocytes. As the simplest model, a 2D monolayer of hPSC-CM has been used to establish the basic response to cardioactive drugs using techniques such as patch clamping [13,14], microelectrode arrays (MEAs) [15], calcium-sensitive dyes [16], voltage-sensitive dyes [17], and impedance measurements [18,19]. Using induced pluripotent stem cell–derived cardiomyocytes (iPSC-CM), researchers have also been able to recapitulate genetically linked disease phenotypes, such as long QT syndrome, which has created the possibility of patient-specific and disease-specific drug screening [15,20–22]. The FDA has already started to outline plans to incorporate the use of hPSC-CM for screening proarrhythmic drugs, and the use of hPSC-CM will likely be

![Cardiomyocyte, Fibroblast, Endothelial cell, ECM](image_url)
integrated as a part of the preclinical drug screening process in the near future [23].

One of the significant drawbacks in using hPSC-CM is the immature or “fetal-like” phenotype of the cells [24]. The electrophysiological properties and force of contraction vary significantly from adult cardiomyocytes, raising questions on the validity of the drug response observed using hPSC-CM [12,25]. While a 2D monolayer of hPSC-CM expresses most of the ion channels that are of interest for drug screening [15], hPSC-CM change ion channel expression levels and drug screening [26]. Many techniques have been developed to induce alignment in cardiomyocytes in 2D. Micropatterned ECM causes circular morphology [26]. Many techniques have been developed to induce alignment in cardiomyocytes in 2D. Micropatterned ECM causes cardiomyocytes to take on an anisotropic morphology, and increased conduction velocity in the longitudinal direction attributed to the formation of intercalated disks [31,32]. Using cardiomyocytes grown on micropatterned thin films, Grosberg et al. [33] formed strips of aligned cardiomyocytes that deformed in the direction of alignment. The deformation can then be used to calculate the stress produced during contraction. Both normal and abnormal conditions of the heart have been explored using this platform [34–36]. Topographical cues such as nanogrooves, nanofibers, or shrink-induced wrinkles also induce cardiomyocyte alignment [37–40]. Aligned cardiomyocytes have been utilized to study physiological action potential propagation and have also shown varied response to isoprenaline compared to non-aligned cardiomyocytes [41,42]. While 2D models lack many of the physiological features of the myocardium, they offer a simple, robust, and potentially useful in vitro platform for drug screening and disease modeling.

4. Three-dimensional models

In order to more fully replicate normal physiology and anatomical structure, cells must be grown in a 3D microenvironment [43]. Advances in tissue engineering methods, particularly in the areas of synthetic biomaterials and microfabrication, have provided unprecedented opportunities to culture cells in 3D, leading to the growing interest in creating 3D microphysiological systems. The use of 3D culture has resulted in improved drug screening capabilities in many systems such as tumor and liver models [44–48]. Three-dimensional models can more accurately recapitulate physiological features of an organ system compared to 2D, and these methods have been applied to creating 3D microphysiological cardiac tissues.

Most tissue engineering approaches make use of scaffolding materials to create a 3D structure, including native ECM components and synthetic polymers. The earliest attempts to create 3D cardiac tissue utilized fetal rat cardiomyocytes and resulted in synchronously contractile constructs [49]. Lee et al. [50] used a catheter balloon to create a 3D cardiac organoid with pumping capacity. Embedding hPSC-CM into 3D constructs also results in synchronously contractile tissue, demonstrating formation of gap junctions and responsiveness to cardioactive drugs [51]. However, much like 2D monolayer cultures, these tissues lack structural organization at the mesoscopic level (Fig. 2), as cardiomyocytes randomly orient within the 3D matrix. Researchers have since developed several techniques using mechanical and electrical stimuli to induce structural alignment of 3D cardiac tissues.

Eschenhagen et al. [52] pioneered the use of load-bearing anchoring points to induce alignment of cardiomyocytes embedded in a gel. Velcro was used to anchor two sides of a collagen gel, and cellular compaction of the gel induced alignment of embryonic chick cardiomyocytes perpendicular to the sides. The concept of load-bearing anchors has resulted in numerous designs using various ECM compositions that have helped engineer aligned cardiac tissue that range from a few hundred microns to several millimeters [53,54]. The deflection of posts can be used to calculate contractile force, and the ease of tissue formation makes these platforms amenable to high-throughput drug screening. While early works utilized animal-derived cardiomyocytes, similar structures have been created using hPSC-CM [55–58]. These cardiac tissues show advanced electrophysiological properties (e.g., increased conduction velocity, intercalated disk formation) and recapitulate many of the physiological contractile properties seen in vivo [59].

Electrical stimulation has also been utilized to induce alignment of cardiomyocytes. Using electrical pulses that mimic that of the native myocardium, Radisic et al. [60] created aligned cardiac tissues that showed enhanced electrical and contractile properties. Using a platform termed the “biowire,” electrical stimulation at a superphysiological rate induced advanced electrophysiological maturation in cardiac tissues derived from hPSC-CM [61]. Electrical stimulation plays a significant role in the maturation of 3D cardiac tissues, and there is growing evidence that providing electrical stimulation in combination with mechanical load or stimulation can further mature these tissues [62,63].

Researchers have also explored the use of scaffold-free 3D culture systems. Cardiomyocyte differentiation protocols that employ

Fig. 2. Three-dimensional cardiac tissue derived from hPSC-CM. (A) Embedding cardiomyocytes in 3D scaffolds result in disorganized structures, as the cardiomyocytes show random sarcomere orientation within the tissue (red = α-sarcomeric actin, blue = DAPI). (B) Using Velcro as an anchor along the edges, the 3D cardiac tissue displays mesoscopic organization and alignment (red = myosin heavy chain, green = sarcomeric α-actinin, blue = DAPI). embryoid bodies (EBs) result in contractile 3D constructs in suspension [64]. Due to the presence of non-myocytes in the differentiated EBs, most researchers dissect and replate the cardiomyocytes onto 2D substrates; however, recent efforts have focused on recreating cardiomyocyte spheroids that can be grown in suspension, making use of techniques such as forced aggregation and hanging-drop culture [65, 66]. These scaffold-free systems lack structural organization but offer a synchronous, cell-dense tissue with the expected response to adrenergic receptor agonists. These small aggregates can also be used as building blocks to efficiently create larger scale tissues, which can potentially reduce the time of culture necessary to form syncytium compared to enzymatically disaggregated cardiomyocytes [57,67]. While these tissues initially lack cellular alignment, load-bearing anchors can be utilized to create aligned, synchronous cardiac tissues. Singularized cardiomyocytes also self-aggregate in suspension to form a cell-dense cardiac tissue. Mathur et al. [68] recently reported the formation of organized cardiac tissue by loading single-cell hPSC-CM in a microfabricated device, which demonstrated a physiological response to cardioactive drugs.

5. Co-culture models

While researchers have succeeded in constructing cardiac tissues with advanced physiological form and function, most of the work has used an incompletely defined population of cells obtained through cardiomyocyte differentiation. As cardiomyocyte differentiation efficiency increases and new purification techniques develop, future studies may have the opportunity to use a pure population of hPSC-CM [69–71]. Interestingly, a pure population of cardiomyocytes is not necessarily the desired starting point. Many other cell types exist within the heart, are abundant in number, and play key roles in the physiological function of the myocardium [72]. Early studies have shown that the presence of non-cardiomyocytes help mature hPSC-CM compared to a pure cardiomyocyte population [73]. The inclusion of more than one cell type complicates the methodology, but should result in more physiologically relevant models, making co-culture systems a critical part of developing microphysiological models [74]. While many functions of non-cardiomyocytes in the heart have been elucidated in vivo, the role of co-culture systems in creating physiologically relevant cardiac tissues remains largely unexplored. This section will describe some of the early efforts in creating co-culture models of the heart, and explore the significance of non-myocytes in microphysiological systems of the myocardium for drug screening (summarized in Fig. 3).

5.1. Endothelial cells

Endothelial cells serve many important functions in the heart. For example, endothelial cells line the interior surfaces of the myocardium (the endocardium) and blood vessels, providing a barrier function that controls communication between the myocardium and blood [9]. A high-density capillary network also exists in the myocardium to meet the large metabolic requirements of the contracting myocardium resulting in a very intimate association between cardiomyocytes and endothelial cells. In fact, every cardiomyocyte is no more than 2–3 μm from a microvascular endothelial cell [75,76].

In addition to their barrier function, endothelial cells extensively communicate with cardiomyocytes in both developing and adult hearts [77]. Many modes of interaction between endothelial cells and cardiomyocytes have been discovered to play critical roles in cardiomyocyte contractility and survival and may be critical in developing microphysiological systems that model cardiomyocyte response to drugs in vitro. Neuregulin-1 (NRG-1) is one of several growth factors produced by cardiac endothelial cells [78]. NRG-1 binds to the epidermal growth factor receptor (EGFR) family of receptors, one of which is ErbB4, expressed by ventricular cardiomyocytes. The binding of NRG-1 to ErbB4 and the signaling cascade through the heterodimerization of ErbB4 with ErbB2 is essential for early cardiac development, as knocking out NRG-1, ErbB4, or ErbB2 in mice models results in developmental failure at embryonic day 10.5 with heart malformation [79–81]. NRG-1 signaling has also been shown to improve differentiation of hPSC toward an atrial/ventricular cardiomyocyte rather than a nodal cell, which is generally desirable for recapitulating the myocardium [82]. A recent study has also shown that the addition of NRG-1/β3 peptides induce maturation of mouse iPSC-CM [83].

The development of the drug trastuzumab (Herceptin), a monoclonal antibody against human ErbB2, helped formulate our understanding and clinical relevance of NRG-1 signaling. Trastuzumab was developed as a chemotherapeutic drug that works by blocking ErbB2, which is overexpressed in some tumor types (e.g., breast cancer), and showed improved efficacy when combined with other chemotherapeutics such as anthracyclines (e.g., doxorubicin) [84]. Due to the cardiotoxic nature of anthracyclines, combinatory chemotherapeutic treatment using trastuzumab raised serious concerns regarding the off-target

Fig. 3. The influence of non-cardiomyocytes and other factors present in the native cardiac microenvironment. Using various modes of communication, cardiomyocyte functions are strongly affected by the presence of endothelial cells, fibroblasts, and other cells and secreted factors. Many of the responses that the cardiomyocytes undergo in the presence of these signals are closely tied to parameters that are commonly used as readouts for detecting cardiotoxicity, highlighting the significance of a complex microphysiological model for capturing a more physiological response to drugs.
cardiac tissue can be created but requires a tri-culture with stromal functions [96,97]. The complex mechanisms involved in regulating cardiomyocyte function may be important for endothelial-cardiomyocyte communication to 2D monolayers. Additionally, Transwells only capture the paracrine effects of endothelial-cell-derived NO has been shown to cause a change in cardiomyocyte contractility in vitro. Endothelial co-culture has proven to be necessary to assess the functional phenotypes of endothelial cells [96,97].

Several other paracrine factors are known to modulate cardiomyocyte function [75,77]. Nitric oxide (NO) released by endothelial cells not only controls vascular tone of blood vessels but also induces positive inotropic effects on cardiomyocytes [92]. Importantly, endothelial-derived NO has been shown to cause a change in cardiomyocyte contractile response to β-adrenergic stimulation,signifying its importance in drug screening applications [93]. NRG-1 signaling on cardiomyocytes upregulates NO synthesis, further influencing cardiomyocyte contractility in the presence of endothelial cells [94]. Finally, endothelin-1 (ET-1) is another positive inotrope released by endothelial cells [95]. ET-1 also increases release of NO and NRG-1 from endothelial cells, demonstrating the complex mechanisms involved in regulating cardiomyocyte functions [96,97].

Most efforts surrounding endothelial-cardiomyocyte co-culture have centered on the goals of creating vascularized cardiac tissue for cell therapy in repairing damaged myocardium [58,98,99]. Transwells have been widely used to study the paracrine effects of endothelial-cardiomyocyte co-culture; however, such systems are mostly limited to 2D monolayers. Additionally, Transwells only capture the paracrine effects of the cells, while evidence exists that contact-mediated signaling may be important for endothelial-cardiomyocyte communication [100]. Using 3D scaffolds that are used in tissue engineering applications, future microphysiological systems will look to scale down these tissues while maintaining the key effects of endothelial-cardiomyocyte co-culture. Co-culturing hPSC-CM with endothelial cells and mesenchymal stem cells improved the contractility and cardiac ion channel expression of the 3D cardiac tissue [101]. Scaffold-free vascularized cardiac tissue can be created but requires a tri-culture with stromal cells in order to prevent endothelial cell death [102]. Recent work by Vollert et al. [103] successfully introduced an endothelial-coated channel through a 3D cardiac tissue. Endothelial co-culture has proven to be valuable in other microphysiological organ systems [104,105], and we believe the same will hold true for cardiac tissues.

The source and phenotype of the endothelial cells used in culture may also play an important role in their function, as endothelial cells differ in function between different organs, but also within different parts of the heart (e.g., microvascular, endocardial, and aortic) [106]. For example, aortic endothelial cells do not express NRG-1 and thus may result in a poor in vitro model when predicting drug-induced cardiotoxicity [97]. While human neonatal and adult endothelial cell sources are readily available, the use of stem cell-derived endothelial cells is also a viable option given the differentiation protocols that have been recently developed [107,108]. Further characterization may be necessary to assess the functional phenotypes of endothelial cells in the context of the cardiac microenvironment.

5.2. Fibroblasts

Fibroblasts are commonly defined as mesenchymal cells that have an elongated morphology and lack a basement membrane [109]. While the exact numbers vary by species, cardiac fibroblasts make up a significant portion of adult mammalian hearts in terms of total number of cells (45 to 70%), exceeding in number that of cardiomyocytes [109–112]. Present throughout the heart, fibroblasts occupy the connective tissue space between cardiomyocytes [112,113]. Cardiac fibroblasts play several key roles in cardiac development and physiology, including ECM remodeling, paracrine signaling, mechanosensing, and electrical coupling.

Cardiac fibroblasts regulate ECM synthesis and degradation, which has been shown to be critical for cardiomyocyte function. The cardiac ECM composition changes throughout development, and further changes in the ECM can be induced in many pathological conditions, such as hypertension [115]. Cardiac fibroblasts also produce peristin, which is highly expressed in the developing heart, and has been shown to induce cardiomyocyte proliferation in vitro and in vivo [116]. Fibronecin, fibrillin, elastin, proteoglycans, and glycoproteins are also present in the cardiac ECM, deposited mainly by cardiac fibroblasts [117,118]. Fibroblasts also secrete matrix metalloproteinases (MMPs) in order to remodel the cardiac ECM. The balance between ECM proteins and MMPs is critical for ECM homeostasis, which can be affected by external factors such as mechanical stimulation [109,119]. A number of pathological conditions such as myocardial infarction and pressure overload induce cardiac fibroblasts to undergo a phenotypic change into myofibroblasts, increasing proliferation and deposition of collagen via a TGFβ mediated pathway [111,117].

Cardiac fibroblasts also directly couple with cardiomyocytes, utilizing connexins to allow propagation of electrical signals [120]. Fibroblasts are able to electrically couple cardiomyocytes separated by up to 300 μm in distance in vitro, although there is considerable debate on the extent of electrical coupling that occurs in vivo between fibroblasts and cardiomyocytes [121,122]. Fibroblast–cardiomyocyte coupling significantly alters electrophysiological properties of cardiomyocytes, affecting conduction speed, resting membrane potential, repolarization, and excitability [123]. The large number of cardiac fibroblasts in the SA node suggests that they also modulate the function of nodal cells. In contrast, fibroblast–cardiomyocyte coupling in the myocardium may be more pathological and has been shown to induce abnormal depolarization and reentry in vitro [124,125]. Further studies must be performed to elucidate the exact role of fibroblast–cardiomyocyte coupling in vivo, such that this function can be recapitulated in vitro.

The role of including cardiac fibroblasts in cardiac microphysiological systems remains unclear. Co-culture of cardiomyocytes with mouse-derived cardiac fibroblasts improved the contractility of engineered cardiac tissues [126]. Adding cardiomyocytes to precultured fibroblasts and endothelial cells results in improved cardiac tissue formation with elongated morphology and increased electrical coupling via Cx43 expression [127,128]. Several studies have reported a population of vimentin-positive cells that are dispersed within 3D cardiac tissues, indicating that these fibroblast-like cells play a role in the formation of these tissues [55,59,129]. While increasing numbers of fibroblasts reduced electrophysiological maturation of cardiac tissues, complete removal of nonmyocytes led to decreased cell spreading and gel compaction in 3D cardiac tissues [130]. A recent study showed that adding 25% CD90+ cells to hPSC-CM resulted in improved cardiac tissue formation and increased cardiomyocyte maturation compared to cardiomyocyte only control [131].

One of the challenges in using fibroblast co-culture models is the heterogeneity of fibroblasts within the body, showing significant variation in function even within a single organ system [118,122,132]. Most researchers have used fibroblast sources that are not of cardiac origin, which may be a concern for recapitulating the physiological microenvironment of the heart. Identifying fibroblasts also poses a challenge; while anti-vimentin antibodies have been widely used to label fibroblasts, endothelial cells also stain positively for such antibodies [133].
5.3. Non-cardiac cells and blood

Red blood cells (RBCs) account for the majority of cells present in blood, serving as oxygen carriers to help deliver oxygen throughout the body. For tissue culture in vitro, most systems rely on diffusion of nutrients, including oxygen, using static exposure to cell culture medium. Due to the low solubility of oxygen in medium lacking oxygen carriers, oxygen depletion is a serious concern in microphysiological systems that employ 3D cardiac tissue and may contribute to abnormal tissue function [43]. Perfusion of medium containing oxygen carriers such as perfluorocarbon can improve contractility of cardiac tissues cultured in vitro [134]. Simple perfusion of media also increases cell survival within 3D cardiac tissues compared to static controls [103,135]. The implementation of other strategies to increase oxygen delivery such as vascularization may be necessary to create and maintain cell-dense cardiac tissues [136,137]. Nonetheless, it remains to be seen whether implementation of such strategies are necessary for microphysiological systems, whose size is at or near the limit of diffusion (~200–250 μm). The inclusion of vascular networks may enable physiological delivery of drugs through blood vessels, which may facilitate our understanding of pharmacokinetics (e.g., how readily drugs diffuse out of blood vessels) as well as potential drug interaction with the endothelial lining of the vessel.

The choice of medium is significant, especially for co-culture systems where different cell types require different nutrients and growth factors. While RPMI1640 supplemented with B-27 is commonly used to differentiate and maintain hPSC-CM, it is a very simple medium that may lack important signaling molecules found in blood. The addition of serum in the media may result in a more physiological media; however, the content of serum is undefined with inherent batch to batch variability, and exposure to serum-containing media can alter hPSC-CM phenotype and drug response to adrenergic receptor agonists [138]. The determination of media composition that promotes physiological behavior of cardiomyocytes grown in vitro will be an essential step in improving the applicability of cardiac microphysiological systems for drug screening.

Finally, no co-culture model has successfully incorporated neuronal cells, which release catecholamines and acetylcholine that directly regulate cardiomyocyte function [139,140]. The ventricles have high sympathetic innervation, and the release of catecholamines (e.g., epinephrine, norepinephrine) results in positive inotropic and chronotropic effects [141]. While the physiological functions of these secreted factors in the heart are established, their significance in creating cardiac microphysiological models remains unclear. Beauchamp et al. reported a decrease in beating rate of cardiomyocyte spheroids over 30 days, while long-term stimulation using phenylephrine (α1-adrenergic receptor agonist) resulted in sustained beating rate over the same period of time [66]. The supplementation of phenylephrine and/or angiotensin-II has also been shown to induce hypertrophic over 30 days, while long-term stimulation using phenylephrine (an adrenergic receptor agonist) resulted in sustained beating rate over the same period of time [66].

5.4. Vascularization

Integrating vascular networks may enable physiological delivery of drugs to cardiovascular tissue, which may facilitate our understanding of pharmacokinetics, how readily drugs diffuse out of blood vessels, and potential drug interaction with the endothelial lining of the vessel. The inclusion of vascular networks may enable physiological delivery of drugs to cardiovascular tissue, which may facilitate our understanding of pharmacokinetics, how readily drugs diffuse out of blood vessels, and potential drug interaction with the endothelial lining of the vessel. The inclusion of vascular networks may enable physiological delivery of drugs to cardiovascular tissue, which may facilitate our understanding of pharmacokinetics, how readily drugs diffuse out of blood vessels, and potential drug interaction with the endothelial lining of the vessel.
